Abstract

This paper discusses the application of category theory as a unifying concept for formally developed information fusion systems. Category theory is a mathematically sound representation technique used to capture the commonalities and relationships between objects. This feature makes category theory a very elegant language for describing information fusion systems and the information fusion process itself. After an initial overview of category theory, the paper investigates the application of category theory to a wavelet based multisensor target recognition system, the Automatic Multisensor Feature-based Recognition System (AMFRS), which was originally developed using formal methods.

1. Introduction

The goal of information fusion is to combine multiple pieces of data in a way so that we can infer more information than what is contained in the individual pieces of data alone. This requires that we be able to determine how the individual pieces of data are related. It would also be nice if we could describe this relationship between data in a formal way so that we can automatically reason over the information fusion process without the use of unreliable and brittle heuristics. In this paper we present category theory as a unifying concept for formally defining information fusion systems. The goal of category theory is to define the relationships between objects within a category of related objects. Category theory also provides operators that allow us to reason over these relationships.

The first section of the paper is a tutorial on algebraic specifications and category theory. Next we describe a formally defined fusion system, the Automatic Multisensor Feature-based Recognition System (AMFRS), and describe how we could incorporate category theory constructs to provide a provably correct technique for implement the system.

2. Theories and Specifications

The notation generally used to capture the formal definitions of systems is a formal specification. There are two types of formal specifications commonly used to describe the behavior of software: operational and definitional. An operational specification is a “recipe” for an implementation that satisfies the requirements while a definitional specification describes behavior by listing the properties that an implementation must posses. Definitional specifications have several advantages over operational specifications.

1. Definitional specifications are generally shorter and clearer than operational specifications.
2. Definitional specifications are easier to modularize and combine.
3. Definitional specifications are easier to reason about, which is the key reason they are used in automated systems.

It is generally recognized that creating correct, understandable formal specifications is difficult, if not impossible, without the use of some structuring technique or methodology. Algebraic theories provide the advantages of definitional specifications along with the desired structuring techniques. Algebraic theories are defined in terms of collections of values called sorts, operations defined over the sorts, and axioms defining the semantics of the sorts and operations. The structuring of algebraic theories is provided by category theory operations and provides an elegant way in which to combine smaller algebraic theories into larger, more complex theories.

Categories are an abstract mathematical construct consisting of category objects and category arrows. In general, category objects are the objects in the category of interest while category arrows define a mapping from the internal structure of one category...
object to another. In our research, the category objects of interest are algebraic specifications and the category arrows are specification morphisms. In this category, \( \text{Spec} \), specification morphisms map the sorts and operations of one algebraic specification into the sorts and operations of a second algebraic specification such that the axioms in the first specification become provable theorems in the second specification. Thus, in essence, a specification morphism defines an embedding of one specification into a second specification.

### 2.1. Algebraic Specification

In this section, we define the important aspects of algebraic specifications and how to combine them using category theory operations to create new, more complex specifications. As described above, category theory is an abstract mathematical theory used to describe the external structure of various mathematical systems. Before showing its use in relation to algebraic specifications, we give a formal definition [8].

**Category.** A category \( C \) is comprised of

- a collection of things called \( C \)-objects;
- a collection of things called \( C \)-arrows;
- operations assigning to each \( C \)-arrow \( f \) a \( C \)-object \( \text{dom} \ f \) (the domain of \( f \)) and a \( C \)-object \( \text{cod} \ f \) (the "codomain" of \( f \)). If \( a = \text{dom} \ f \) and \( b = \text{cod} \ f \) this is displayed as \( f: a \rightarrow b \) or \( a \xrightarrow{f} b \);
- an operation, \( \circ \), called composition, assigning to each pair \( \langle g, f \rangle \) of \( C \)-arrows with \( g = \text{cod} \ f \) a \( C \)-arrow \( g \circ f \) \( \text{dom} \ f \rightarrow \text{cod} \ g \), the composite of \( f \) and \( g \) such that the Associative Law holds: Given the configuration

\[
\begin{array}{cccc}
  a & \rightarrow & b & \rightarrow & c & \rightarrow & d \\
\end{array}
\]

of \( C \)-objects and \( C \)-arrows, then

\[
h \circ (g \circ f) = (h \circ g) \circ f.
\]

- an assignment to each \( C \)-object, \( b \), a \( C \)-arrow, \( \text{id}_{b} \), called the identity arrow on \( b \), such that the Identity Law holds: For any \( C \)-arrows \( f: a \rightarrow b \) and \( g: b \rightarrow c \)

\[
\text{id}_{a} \circ f = f \quad \text{and} \quad g \circ \text{id}_{b} = g.
\]

#### 2.1.1. The Category of Signatures

In algebraic specifications, the structure of a specification is defined in terms of an abstract collection of values, called sorts and operations over those sorts. This structure is called a signature [9]. A signature describes the structure that an implementation must have to satisfy the associated specification; however, a signature does not specify the semantics of the specification. The semantics are added later via axiomatic definitions.

**Signature.** A signature \( \Sigma = (S, \Omega) \) consists of a set \( S \) of sorts and a set \( \Omega \) of operation symbols defined over \( S \). Associated with each operation symbol is a sequence of sorts called its rank. For example, \( f: s_{1}, s_{2}, \ldots, s_{n} \rightarrow s \) indicates that \( f \) is the name of an \( n \)-ary function, taking arguments of sorts \( s_{1}, s_{2}, \ldots, s_{n} \) and producing a result of sort \( s \). A nullary operation symbol, \( c: \rightarrow s \), is called a constant of sort \( s \).

An example of a signature is shown in Figure 1. In the signature \( \text{Ring} \) there is one sort, \( \text{ANY} \), and five operations defined on the sort.

```plaintext
signature Ring is
sorts ANY
operations
  plus : ANY \times ANY \rightarrow ANY
  times : ANY \times ANY \rightarrow ANY
  inv : ANY \rightarrow ANY
  zero : \rightarrow ANY
  one : \rightarrow ANY
end
```

#### Figure 1. Ring Signature

In our research, signatures define the required structure for formally describing wavelet-based models. Signatures provide the ability to define the internal structure of a specification; however, they do not provide a method to reason about relationships between specifications. To create a theory of information fusion using algebraic specifications, operations to define relations between specifications must be available. There must be a well-defined theory about how to reason about the external structure of these specifications (i.e., how they relate to one another).

As might be expected, signatures (as the “\( C \)-objects”) with the correct “\( C \)-arrows” form a category that is of great interest in our research. For signatures, the \( C \)-arrows are called **signature morphisms** [9]. Signatures and their associated signature morphisms form the category, \( \text{Sign} \).

**Signature Morphism.** Given two signatures \( \Sigma = (S, \Omega) \) and \( \Sigma' = (S', \Omega') \), a signature morphism \( \sigma: \Sigma \rightarrow \Sigma' \) is a pair of functions \( \sigma_{S}: S \rightarrow S' \), \( \sigma_{\Omega}: \Omega \rightarrow \Omega' \), mapping sorts to sorts and operations to operations such that the sort map is compatible with the ranks of the operations, i.e., for all operation symbols \( f: s_{1}, s_{2}, \ldots, s_{n} \rightarrow s \) in \( \Omega \), the operation symbol \( \sigma_{\Omega}(f): \sigma_{S}(s_{1}), \sigma_{S}(s_{2}), \ldots, \sigma_{S}(s_{n}) \rightarrow \sigma_{S}(s) \) is in \( \Omega' \). The composition of two signature morphisms, obtained by
implement a program nor does it define an implementation. A specification only defines the semantics required of a valid implementation. In fact, for most specifications, there are a number of implementations that satisfy the specification. Implementations that satisfy all axioms of a specification are called models of the specification [9]. To formally define a model, we first define a \( \Sigma \)-algebra [9].

\( \Sigma \)-algebra or \( \Sigma \)-model. Given a signature \( \Sigma = (S, \Omega) \), a \( \Sigma \)-algebra \( A = (A_s, F_s) \) consists of two families:

- a collection of sets, called the carriers of the algebra, \( A_s = \{A_s | s \in S\} \); and
- a collection of total functions, \( F_s = \{f_s | f \in \Omega\} \) such that if the rank of \( f \) is \( s_1, s_2, \ldots, s_n \rightarrow x \), then \( f_s \) is a function from \( A_{s_1} \times A_{s_2} \times \ldots \times A_{s_n} \) to \( A_x \). (The symbol \( \times \) indicates the Cartesian product of sets here.)

Model. A model of a specification \( SP = (\Sigma, \Phi) \) is a \( \Sigma \)-algebra, \( M \), such that \( M \) satisfies each \( \Sigma \)-sentence (axiom) in \( \Phi \). The collection of all such models \( M \) is denoted by \( \text{Mod}[SP] \). The sub-category of \( \text{Mod}(\Sigma) \) induced by \( \text{Mod}[SP] \) is also denoted by \( \text{Mod}[SP] \).

An example of a specification is shown in Figure 4. This specification is the original \( \text{RING} \) signature of Figure 1 enhanced with the axioms that define the semantics of the operations. Valid models of this specification include the set of all integers, \( \mathbb{Z} \), with addition and multiplication as well as the set of integers modulo 2, \( \mathbb{Z}_2 = \{0, 1\} \), with the inverse operation (\( - \)) defined to be the identity operation.

As signatures have signature morphisms, specifications also have specification morphisms. Specification morphisms are signature morphisms that ensure that the axioms in the source specification are theorems (are provable from the axioms) in the target specification. Showing that the axioms of the source specification are theorems in the target specification is a proof obligation that must be shown for each specification morphism. Specifications and specification morphisms enable the creation and modification of specifications that correspond to valid signatures within the category \( \text{Sign} \). However, before we can formally define a specification morphism, we must first define a reduct [9].

2.1.2. The Category of Specifications

To model semantics, signatures are extended with axioms that define the intended semantics of the signature operations. A signature with associated axioms is called a specification [9].

Specification. A specification \( SP \) is a pair \( (\Sigma, \Phi) \) consisting of a signature \( \Sigma = (S, \Omega) \) and a collection \( \Phi \) of \( \Sigma \)-sentences (axioms).

Although a specification includes semantics, it does not implement a program nor does it define an
spec    Ring is
sorts   ANY
operations
   As defined in Figure 2
axioms
   \forall a,b,c \in \text{ANY}
   a \text{ plus} (b \text{ plus} c) = (a \text{ plus} b) \text{ plus} c
   a \text{ plus} b = b \text{ plus} a
   a \text{ plus} zero = a
   a \text{ plus} (\text{inv} a) = \text{zero}
   a \text{ times} (b \text{ times} c) = (a \text{ times} b) \text{ times} c
   a \text{ times} one = a
   a \text{ times} (b \text{ times} c) = (a \text{ times} b) \text{ times} c
   a \text{ plus} (b \text{ plus} c) = (a \text{ times} b) \text{ plus} (a \text{ times} c)
   (a \text{ plus} b) \text{ times} c = (a \text{ times} c) \text{ plus} (b \text{ times} c)
end

Figure 4. Ring Specification

Reduct. Given a signature morphism \( \sigma: \Sigma \rightarrow \Sigma' \) and a \( \Sigma' \) -
algebra \( A' \), the \( \sigma \)-reduct of \( A' \), denoted \( A'|_{\sigma} \), is the \( \Sigma \) -
algebra \( A = (A_\Sigma, F_\Sigma) \) defined as follows (with \( \Sigma = (S, \Omega) \)):

\[
A_\Sigma = A_{\sigma|S} \text{ for } s \in S, \text{ and } \\
f_\Sigma = (\sigma(f))_\Sigma \text{ for } f \in \Omega
\]

A reduct defines a new \( \Sigma \)-algebra (or \( \Sigma \)-model) from
an existing \( \Sigma' \)-algebra. It accomplishes this by
selecting a set or functions for each sort or operation
in \( \Sigma \) based on the signature morphism from \( \Sigma \) to \( \Sigma' \).
Thus if we have a signature, \( \Sigma' \), and a \( \Sigma '-\)model, we can create a \( \Sigma '-\)model for a second signature, \( \Sigma \), by
defining a signature morphism between them and
taking the reduct based on that signature morphism.
A reduct is now used to extend the concept of a
signature morphism to form a specification morphism
[9].

Specification Morphism. A specification morphism from a
specification \( SP = (\Sigma, \Phi) \) to a specification \( SP' = (\Sigma', \Phi') \)
is a signature morphism \( \sigma: \Sigma \rightarrow \Sigma' \) such that for every
model \( M \in \text{Mod}[SP] \), \( M|_{\sigma} \in \text{Mod}[SP'] \). The specification
morphism is also denoted by the same symbol, \( \sigma: \Sigma \rightarrow \Sigma' \).

We now turn to the definition of theories and theory
presentations. Basically a theory is the set of all
axioms that logically follow from a given set of
axioms [8]. A theory presentation is a specification
whose axioms are sufficient to prove all the theorems
in a desired theory but nothing more. Put succinctly,
a theory presentation is a finite representation of a
possibly infinite theory. To formally define a theory
and theory presentation we must first define logical
consequence and closure [8].

Logical Consequence. Given a signature \( \Sigma \), a \( \Sigma \)-sentence
\( \varphi \) is said to be a logical consequence of the \( \Sigma \)-sentences
\( \varphi_1, \ldots, \varphi_n \) written \( \varphi_1, \ldots, \varphi_n \models \varphi \), if each \( \Sigma \)-algebra that
satisfies the sentences \( \varphi_1, \ldots, \varphi_n \) also satisfies \( \varphi \).

Closure, Closed. Given a signature \( \Sigma \), the closure,
closure(\( \Phi \)), of a set of \( \Sigma \)-sentences \( \Phi \) is the set of all \( \Sigma \)-
sentences which are the logical consequence of \( \Phi \), i.e.,
closure(\( \Phi \)) = \{ \varphi | \Phi \models \varphi \}. A set of \( \Sigma \)-sentences \( \Phi \) is said to
be closed if and only if \( \Phi = \text{closure}(\Phi) \).

Theory, Presentation. A theory \( T \) is a pair \( \langle \Sigma, \text{closure}(\Phi) \rangle \)
consisting of a signature \( \Sigma \) and a closed set of \( \Sigma \)-sentences,
closure(\( \Phi \)). A specification \( \langle \Sigma, \Phi \rangle \) is said to be a
presentation for a theory \( \langle \Sigma, \text{closure}(\Phi) \rangle \). A model of a
theory is defined just as for specifications; the collection
of all models of a theory \( T \) is denoted \( \text{Mod}[T] \). Theory
morphisms are defined analogous to specification
morphisms.

Specification morphisms complete the basic tool set
required for defining and refining specifications.
This tool set can now be extended to allow the
combination, or composition, of existing
specifications to create new specifications. This is
where category theory is extremely useful in
information fusion. Often two specifications that
were originally extensions from the same ancestor
need to be combined. Therefore, the desired
combined specification consists of the unique parts
of two specifications and some “shared part” that is
common to both specifications (the part defined in
the shared ancestor specification). This combining
operation is called a colimit [8]. The colimit
operation creates a new specification from a set of
existing specifications. This new specification has all
the sorts and operations of the original set of
specifications without duplicating the “shared” sorts
and operators. To formally define a colimit, we must
first define a cone (or cocone) [8].

Cone. Given a diagram \( D \) in a category \( C \) and a \( C \)-object \( c \),
a cone from the base \( D \) to the vertex \( c \) is a collection of
arrows \( \{ f_i: d_i \rightarrow c \ | \ d_i \in D \} \), one for each object \( d_i \) in
the diagram \( D \), such that for any arrow \( g: d_i \rightarrow d_j \) in \( D \),
the diagram shown in Figure 5 commutes i.e., \( g \circ f_i = f_j \).

Colimit. A colimit for a diagram \( D \) in a category \( C \) is a \( C \)-
object \( c \) along with a cone \( \{ f_i: d_i \rightarrow c \ | \ d_i \in D \} \) from \( D \) to \( c \)
such that for any other cone \( \{ f'_i: d_i \rightarrow c' \ | \ d_i \in D \} \) from \( D \) to
a vertex \( c' \), there is a unique \( C \)-arrow \( f: c \rightarrow c' \) such that for
every object \( d_i \) in \( D \), the diagram shown in Figure 6
commutes (i.e., \( f \circ f'_i = f_i \)).
Conceptually, the colimit of a set of specifications is
the “shared union” of those specifications based on
the morphisms between the specifications. These
morphisms define equivalence classes of sorts and
operations. For example, if a morphism for
specification A to specification B maps sort α to sort β,
then α and β are in the same equivalence class and
thus is a single sort in the colimit specification of A,
B, and the morphism between them. Therefore, the
colimit operation creates a new specification, the
colimit specification, and a cone morphism from each
specification to the colimit specification. These cone
morphisms satisfy the condition that the translation of
any sort or operation along any of the morphisms in
the diagram leading to the colimit specification is
equivalent. An example of the colimit operation is
shown in Figure 7 and Figure 8. Given the Bin-Rel,
Reflexive, and Transitive specifications in Figure
7, the “colimit specification” would be the Pre-Order
specification shown as the diagram in Figure 8. Notice that the sorts E, X, and T belong to
the same equivalence class in Pre-Order. Likewise,
the operations •, =, and < also form an equivalence
class in Pre-Order. Thus Pre-Order defines a
specification with one sort, \{E, X, T\} and one
operation, \{•, =, <\}, which is both transitive and
reflexive. The specification Bin-Rel defines the
“shared” parts of the colimit but adds nothing to the
final specification.

A category in which the colimit of all possible C-
objects and C-arrows exists is called cocomplete. As
shown by Goguen and Burstall [2, 3], the category
Sign and Spec are both cocomplete; therefore, the
colimit operation may be used freely within the
category Spec to define the construction of complex
theories from a group of simpler theories.

Using morphisms, extensions, and colimits as a basic

tool set, there are a number of ways that
specifications can be constructed [9, 4]:
1. Build a specification from a signature and a set of axioms;
2. Form the union of a collection of specifications;
3. Translate a specification via a signature morphism;
4. Hide some details of a specification while preserving its models;
5. Constrain the models of a specification to be minimal;
6. Parameterize a specification; and
7. Implement a specification using features provided by others.

Many of these methods are useful in specifying and implementing information fusion systems. For instance, if we can define the shared part of two types of data, we can formally combine them using a colimit.

2.2. Functors

The previous sections defined the basic categories and construction techniques used to build large-scale software specifications. In this section, we extend these concepts further to define models of specifications and how they are related to the construction techniques used to create their specifications. Before describing this relationship, we define the concept of a functor that maps C-objects and C-arrows from one category to another in such a way that the identity and composition properties are preserved [7].

Functor. Given two categories \(A\) and \(B\), a functor \(F: A \rightarrow B\) is a pair of functions, an object function and a mapping function. The object function assigns to each object \(X\) of category \(A\) an object \(F(X)\) of category \(B\); the mapping function assigns to each arrow \(f: X \rightarrow Y\) of category \(A\) an arrow \(F(f): F(X) \rightarrow F(Y)\) of category \(B\). These functions satisfy the two requirements:

\[
F(1_X) = 1_{F(X)}
\]

for each identity \(1_X\) of \(A\)

\[
F(g \circ f) = F(g) \circ F(f)
\]

for each composite \(g \circ f\) defined in \(A\)

Basiclly a functor is a morphism of categories. Actually, we have already presented two functors: the \(\text{reduct}\) functor that maps models of one specification (in the category \(\text{Mod}[X_1]\)) into models of a second specification (in the category \(\text{Mod}[X_2]\)) and the \(\text{models}\) functor that maps specifications in the category \(\text{Spec}\) to their category of models, \(\text{Mod}[X]\), in \(\text{Cat}\), the category of all sufficiently small categories.

3. Automatic Multisensor Feature-based Recognition System

To show applicability of the category theoretic notions described above to information fusion systems, we will discuss a case study of Automatic Multisensor Feature-based Recognition System (AMFRS) [6], which was originally developed using a model-based approach. In this case study, we transform the AMFRS framework into an equivalent system using a category theoretic approach. First we will discuss the original system and then show its equivalent structure using algebraic specifications and category theory.

3.1. Model-Theory Based Framework

In the original model-based development approach, wavelet-based models were developed for integration into the AMFRS to help recognize targets. AMFRS uses a model-based framework to describe how to combine information contained in the wavelets for use in the system. Within this framework, models were developed to help recognize targets based on wavelet coefficients that could be interpreted as meaningful features of the target.

In this framework, models were developed based on a \(\text{language}\) and its associated \(\text{theory}\) that described the semantics of the language. To combine languages and theories, three operators are used: reduction, expansion, and union. In general, the \(\text{reduction}\) operator removes symbols from a language along with all the sentences in which it exists in its associated theory. Expansion is the opposite. \(\text{Expansion}\) allows us to add symbols and new sentences about those symbols to the language. Finally, the \(\text{union}\) operator combines the symbols and sentences from two different language/theory pairs into a single language and a single theory.

Using these operators, Korona created a framework for combining languages and theories about two different types of sensor data into a single fused language and theory. This framework is shown in Figure 9. In Figure 9, we show only the language composition process. The theory fusion process is identical. In this example, we assume there are two sensors whose data is described by two languages \(L_r\) and \(L_c\). These languages are extended to the languages \(L_{r'}\) and \(L_{c'}\) by adding symbols denoting operations on a subset of the wavelet coefficients used to describe the sensor data. These subsets of coefficients represent those coefficients that will be
operators also have counterparts in category theory. The model values used in the operations.

The result of this is that the shared parts of the two specifications are not duplicated.

Figure 9. Model-Theory Based Framework

After the necessary symbols have been added to the languages, \( L_e^r \) and \( L_i^f \) are reduced by removing all the symbols not related to the coefficients selected for use in the final fused language. The new reduced languages, \( L_e^{\sigma^r} \) and \( L_i^{\sigma^r} \), are then combined into a single language, \( L_{ri} \), by the union operation. This language contains all the symbols representing the coefficients and operations on them required to construct the final fused language.

The basic operator in category theory is the morphism. In the category of \( Spec \), which includes all possible algebraic specifications, these morphisms are specification morphisms that define how one specification is embedded in a second specification. That is, it defines a mapping from the sorts and operations of the first specification into the sorts and operations of the second specification in such a way as to ensure the axioms of the first specification are theorems of the second specification (i.e., the axioms hold in the second specification under the defined mapping of sorts and operations). Thus a specification morphism can be used to define an expansion as well as a reduction (they are basically inverses of each other). If we have an expansion of specification \( A \) into specification \( B \), in effect we have a morphism from \( A \) to \( B \). Likewise, a reduction of specification \( A \) to specification \( B \), indicates morphism from \( B \) to \( A \). The language union operator can also be modeled easily using the category theory colimit operation. The colimit operation combines two (or more) specifications, automatically creating a morphism between the original specifications and the resulting colimit specification. If two specifications being combined using a colimit operation share common parts (e.g., they both use integers), these parts can be specified as common by defining morphisms from the common, or shared, specification to the individual specifications. This shared specification, along with the associated morphisms, are included in the colimit operation. The result of this is that the shared parts of the two specifications are not duplicated.

The conversion of the model-based framework into a category theoretic framework is shown in Figure 10. In this framework, the languages and their associated theories are converted to algebraic specifications (or theory presentations) and reductions and extensions are converted to morphisms. Note that a reduction from \( A \) to \( B \) results in a morphism from \( B \) to \( A \). The union operation is converted to a colimit operation. The \( S \) specification denotes any shared part of specifications \( T_i^{\sigma^r} \) and \( T_i^{\sigma^t} \). In this case it might include domain information about wavelets, targets, etc.

Figure 11 represents a simplification of the category theoretic setting shown in Figure 10. Basically, the morphisms \( \sigma_1, \sigma_4, \) and \( \sigma_8 \) from Figure 10 have been combined into morphism \( \sigma_{15} \) of Figure 11. This is possible since all the sorts, operations, and axioms removed by \( \sigma_1 \) and \( \sigma_4 \) can be carried along without changing the semantics. As we see when we get to the model creation phase, carrying along these extra sorts, operations, and axioms will become an advantage.
4. Implications

There are many positive implications of putting the AMFRS design into a category theoretic setting. First, there is no information loss in translating languages and theories into algebraic specifications. In fact, we gain modeling ability by adding the notion of a sort. By using sorts, we can precisely define operation signatures. Also, the notions of morphisms, definitional extensions, colimits, and interpretations give us a wide variety of tools with well-defined meanings. We can prove when morphisms and definitional extensions exist as well as construct the resulting colimit specification based on a set of specifications and morphisms. All in all, category theory provides us a much greater capability to prove relationships between specifications. Finally, the categorical setting allows us to construct,
in a provably correct manner, consistent sets of models required by the AMFRS system. All we have to do is construct one specific model and the models required by AMFRS can be generated automatically. The bottom line is, you lose nothing and gain a lot by using algebraic specifications and category theory in the development of formal information fusion systems such as AMFRS.
